Chapter 6 - Valuing Levered Projects

Carlos Miguel Dos Santos Oliveira Ståle Størdal Felipe Van de Sande Araujo **First analyses**

Financing rules & discount rates

Calculating project value with different debt ratio

Examples

Finance - investment interactions

Concern very common business decisions:

- ▶ Telecom Co. wants to build new mobile network
 - but finance the investment with more debt
- ► Transport company considers fleet expansion
 - but wants to lease, not buy the trucks
- Oil company wants to diversify into green energy
 - project has very different risk characteristics
 - different debt ratio also

Structure of decision problem

- **1.** Accept project if its NPV>0
- 2. to calculate NPV we need:
 - **2.1** cash flows (usually available)
 - **2.2** discount rate (chapter's topic)
- **3.** Discount rate depends on:
 - **3.1** business risk or, equivalently, the OCC
 - **3.1.1** calculated from existing operations if business risk is the same
 - **3.1.2** otherwise, has to be estimated from other companies
 - **3.2** financial risk, allocation of debt and equity
 - **3.2.1** depends on debt ratio
 - **3.2.2** and financing rule (predetermined of rebalanced)

Some important concepts

- Business risk: reflects the uncertainty of cash flows generated by firm's assets e.g. risk of oil company, software house, construction company...
- Opportunity costs of capital:
 is the reward for bearing business risk
 shareholder's expect return for all equity financed firm
 efficient prices when expected return equals OCC
- Financial risk:
 debtholders have priority over shareholders
 shareholders bear extra financial risk
 adjusted OCC by low risk-return and high risk-return

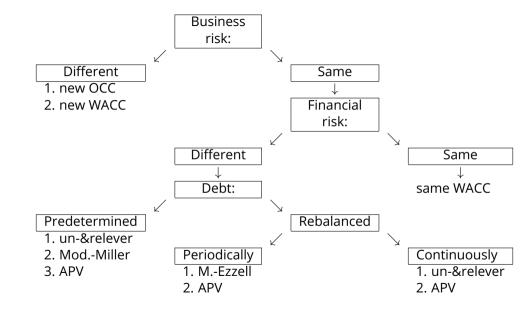

Discount rates

- $ightharpoonup r_a = opportunity cost of capital$: expected rate of return for an equivalent business risk on all-equity financed assets
- WACC after tax weighted average cost of capital
 - ► WACC calculates the unlevered after tax cash flows
 - ▶ WACC can be used with assets that have the same risk and debt ratio

$$WACC = r_e \frac{E}{V} + r_d (1 - \tau) \frac{D}{V}$$
 (1)

- $ightharpoonup r_d = \text{cost of debt}$
- $ightharpoonup r_e = {\sf cost}$ of equity, subscript u/I for (un)levered
- $ightharpoonup au = ext{corporate tax rate (constant, no personal taxes)}$

Basic approaches

- When business risk changes:
 - ightharpoonup calculate new opportunity cost of capital / new asset β
 - ightharpoonup taking leverage into account (unlever β s, example later)
 - remember: proper β is project β (not necessarily company β)
- ▶ When debt ratio increases *given business risk*, two paths:
 - 1. Adjust the discount rate downwards, to include value of interest tax shields
 - 2. Adjust the present value with side effects called *Adjusted Present Value*.

Procedure

Can be obtained:

- the returns for existing firm(s): r_e and r_d
- ightharpoonup and relative sizes of equity and debt: V_e/V and V_d/V

We must know (or make assumptions about):

- the project's financial policy (rebalanced or predetermined debt)
- the interest rate and D/E ratio for the new project

We can then calculate the project value

- by adjusting the WACC (stepwise or with a formula)
- or by using APV

Adjusted Present Value

To calculate Adjusted Present Value:

- **1.** First calculate *base case* value of project as if all equity financed (unlevered) and without *side effects*
- **2.** Then add the present value of the side effects.

Side effects can be anything: tax shields, issue costs, effects on other projects, agency costs, fees to stock exchange, etc.

In case of taxes:

- 1. first calculate the value as if all-equity financed
- 2. then calculate the value of tax shields

We will concentrate on tax shields here, but include some examples of other side effects

Value of tax shields

It depends on the financing rule followed by the firm:

- 1. Money amounts of debt *predetermined*, following a schedule
 - **1.1** repayments and interest follow schedule
 - **1.2** tax shields tied to interest payments
 - ⇒ cost of debt is the appropriate discount rate
 - ⇒ because equity varies, debt ratio varies and WACC varies.
- 2. Debt *rebalanced* to a constant fraction of future project values
 - 2.1 money amount of debt goes up and down with project value
 - **2.2** tax shields also tied to fortunes of the project
 - \Rightarrow incorporate business risk
 - ⇒ discount at the opportunity cost of capital

Working with APV

Base case

- Project gives perpetual risky cash flow (EBIT) of 1562.5 per year
- Requires an investment of 8000
- ► Tax rate is 20%, risk of assets requires a return of 15%
- $r = r_a = r_{e,u} = .15$

Value of the 'unlevered' cash flows:

$$\frac{(1-.2)\times 1562.5}{.15} = \frac{1250}{.15} = 8333$$

Base case NPV = 8333 - 8000 = 333

Side effect: Issue costs

- Firm issues equity to finance the project
- Issue costs are 7.5%

Has to issue shares in the value of

$$\frac{100}{100 - 7.5} \times 8000 = 8649$$

and pay 649 to collect 8000

► APV = 333 - 649 = -316

Side effect: Tax shields

- Project has debt target of 50%
- Take a perpetual loan of 4000, predetermined money amount

Now, issue costs are

$$4000 \times \frac{100}{92.5} = 4324 - 4000 = 324$$

- ▶ Interest rate 10%, yearly interest charge 400
- ► Tax advantage interest: $.2 \times 400 = 80$ Debt fixed: discount at $r_d \Rightarrow$ value tax shields: $\frac{80}{.1} = 800$
- ► APV = 333 324 + 800 = 809

Rebalanced debt

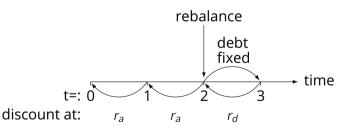

What if debt is rebalanced every year?

- We know the first year's tax shield: 80
 - ► Have to discount to present (t_0) at $r_d = 10\%$
- ► At the end of the first year, debt is rebalanced to 50% of project value (unknown now)
 - then second year's tax shield is know:
 - discount year 2 to year 1 (t_1) with r_d
 - but it is uncertain how project value develops in year 1:
 - discount year 1 to present (t_0) with r_a :

$$\underbrace{\frac{80}{(1+.15)} \times (1+.1)}_{yr.1-rebal.} \times \underbrace{(1+.1)}_{yr.2-fixed}$$

At the end of the second year, debt is rebalanced to 50% of project value (unknown now)

- then third year's tax shield is know:
- ightharpoonup discount year 3 to year 2 (t₂) with r_d
- but project value development in years 1 and 2 uncertain:
- ightharpoonup discount year 1 and 2 to present (t_0) with r_a

In formula:

$$\frac{80}{(1+.15)^2\times(1+.1)}$$

More generally:

$$\frac{80}{1+r_d} + \frac{80}{(1+r_a)(1+r_d)} + \frac{80}{(1+r_a)^2(1+r_d)} + \dots$$

Sum of this series calculated in 2 steps:

- \triangleright discount at r_a , the opportunity cost of capital
- ▶ multiply result by: $\frac{1+r_a}{1+r_d}$

For our project:

$$\frac{80}{.15} = 533 \times \frac{1.15}{1.1} = 557$$

► APV = 333 + (- 324) + 557 = 566

First analyses

Financing rules & discount rates

Calculating project value with different debt ratio

Examples

Procedure

Can be obtained:

- the returns for existing firm(s): r_e and r_d
- ightharpoonup and relative sizes of equity and debt: V_e/V and V_d/V

We must know (or make assumptions about):

- the project's financial policy (rebalanced or predetermined debt)
- the interest rate and D/E ratio for the new project

We can then calculate the project value

- by adjusting the WACC (stepwise or with a formula)
- or by using APV

The rationale is simple:

- 1. To calculate the project's value, we need the project's WACC
- **2.** to calculate WACC, we need the cost of equity, r_e
- **3.** to calculate cost of equity, we need the OCC $r = r_a$
- **4.** OCC can be calculated from existing operations, if the business risk is the same

So we start at the bottom, with the OCC

We also need project details:

- project's debt ratio (decided by management)
- project's financing rule (decided by management)
- project's cost of debt (bank will give an offer)

Adjusting the discount rate: Predetermined debt

Consider the following balance sheet:

Value assets	= V _a	debt	= D
Value tax shields	PV(TS)	equity	= E
total value	= V	total value	= V

Predetermined debt amounts mean tax shields just as risky as debt itself \Rightarrow discount with r_d

We can write the balance sheet in terms of weighted average costs of capital:

$$r_a V_a + r_d PV(TS) = r_e E + r_d D \tag{2}$$

Rearranging terms gives expressions for r_a and r_e :

$$r_a = r_e \frac{E}{V_a} + r_d \frac{D - PV(TS)}{V_a} \tag{3}$$

$$r_a \frac{V_a}{V} = r_e \frac{E}{V} + r_d \frac{D - PV(TS)}{V}$$

and for r_e :

$$r_e = r_a + (r_a - r_d) \frac{D - PV(TS)}{E}$$
(4)

These are general expressions that can also be used for projects of limited life.

But they are not very practical:

- call for the value of tax shields
- usually not known before project value is calculated
- except under MM assumption that debt is also permanent

If debt is also permanent (as well as predetermined), the present value of the tax shields is

$$PV(TS) = \frac{\tau(r_d D)}{r_d} = \tau D \tag{5}$$

Substituting (5) in (3) and (4) gives the Modigliani-Miller expressions for r_e and r_a :

$$r_{e} = r_{a} + (r_{a} - r_{d}) \frac{D - PV(TS)}{E} = r_{a} + (r_{a} - r_{d}) \frac{D - \tau D}{E}$$

$$r_{e} = r_{a} + (r_{a} - r_{d})(1 - \tau) \frac{D}{E}$$
(6)

i.e. MM proposition 2 with taxes

and for r_a :

$$r_{a}\frac{V_{a}}{V} = r_{e}\frac{E}{V} + r_{d}\frac{D - PV(TS)}{V}$$

$$= r_{e}\frac{E}{V} + r_{d}\frac{D - \tau D}{V}$$

$$r_{a}\frac{V_{a}}{V} = r_{e}\frac{E}{V} + r_{d}(1 - \tau)\frac{D}{V} = WACC$$
(7)

WACC formula (7) can be re-written in 2 ways:

1 Gives an explicit relation between r_a and r' (exact for fixed and permanent values)

$$r_a rac{V_a}{V} = WACC$$
 $r_a rac{V - au D}{V} = WACC$
 $r_a \left(1 - au rac{D}{V}
ight) = WACC$

Defining L = D/V, i.e. the debt-value ratio, we get the Modigliani-Miller formula:

$$WACC = r_a(1 - \tau L)$$

MM formula can be used to 'unlever' and 'relever':

- ightharpoonup given the WACC, formula can be used to calculate r_a the opportunity cost of capital
 - ▶ in most given situations, r_e , r_d and τ are (in principle) observable
 - $ightharpoonup r_a$ is not
- $ightharpoonup r_a$ can then be used to calculate WACC for a different debt ratio

Modigliani-Miller formula can also be derived by substituting MM prop. 2 (6) into WACC (7)

2 Second way to rewrite WACC formula gives alternative expression for r_a :

$$r_a = r_d(1-\tau)\frac{D}{V-\tau D} + r_e\frac{E}{V-\tau D}$$

We can do the analysis in terms of β , given the same assumptions:

$$eta_e = eta_a + (1- au)(eta_a - eta_d)rac{D}{E}$$

$$\beta_a = \beta_d (1 - \tau) \frac{D}{V - \tau D} + \beta_e \frac{E}{V - \tau D}$$

Adjusting the discount rate: rebalanced debt

1) Continuous Rebalancing

We use the same balance sheet as before

Value assets	$= V_A$	debt	= D
Value tax shields	PV(TS)	equity	= E
total value	= V	total value	= V

Continuous rebalancing means:

- tax shields just as risky as the assets
- proportion of total value in assets vs. tax shields irrelevant
- taxes drop out of the equation
- opportunity cost of capital is simply the weighted average of the costs of debt and equity:

$$r_a \frac{V_a}{V} + r_a \frac{PV(TS)}{V} = r_a = r_d \frac{D}{V} + r_e \frac{E}{V}$$

Identical to MM prop.2 without taxes, but in a world with taxes!

$$r_e = r_a + (r_a - r_d) \frac{D}{E}$$

Can also be rewritten in terms of β :

$$eta_e = eta_a + (eta_a - eta_d) rac{D}{E}$$

2) Periodical rebalancing

- If debt is rebalanced once per period
- ► Tax shield over the next period is known: $\tau r_d D$
 - ▶ should be discounted at r_d : $\tau r_d D/(1 + r_d)$
- Tax shields further in future are uncertain
 - ightharpoonup should be discounted with r_a

Gives following balance sheet identity in return terms:

$$V_{a}r_{a} + \underbrace{\frac{\tau r_{d}D}{1 + r_{d}}r_{d}}_{next \ period} + \underbrace{\left(PV(TS) - \frac{\tau r_{d}D}{1 + r_{d}}\right)r_{a}}_{further \ periods} = r_{e}E + r_{d}D$$

Rewriting (using $V_a = E + D - PV(TS)$) gives expression for r_e :

$$r_e = r_a + (r_a - r_d) \frac{D}{E} \left(1 - \frac{\tau r_d}{1 + r_d} \right)$$
 (8)

The formula for the WACC can be obtained by substituting (8) into (1):

$$WACC = r_a - \frac{D}{V}r_d\tau \left(\frac{1+r_a}{1+r_d}\right)$$
 (9)

This formula is known as the Miles-Ezzell formula

The Miles-Ezzell formula assumes that debt is rebalanced discretly. It can be used in the same way as MM for unlevering and relevering:

- ightharpoonup for a given WACC, formula gives r_a the opportunity cost of capital
- ightharpoonup given r_a , the formula can be used to calculate WACC for a different debt ratio (and different cost of debt)

First analyses

Financing rules & discount rates

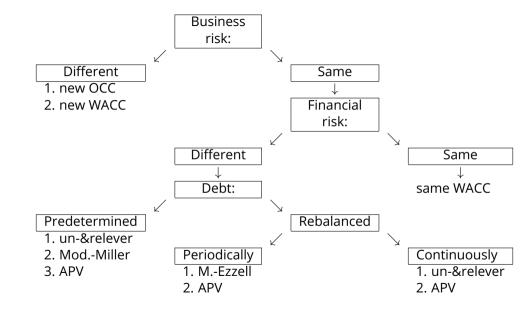

Calculating project value with different debt ratio

Examples

Valuing project with different debt ratios

- Recall that this requires business risk to remain the same
- ▶ The method choice depends on the characteristics of the project
- One main distinction is whether
 - debt amounts are predetermined
 - or vary with project value
- Formulas for perpetuities can be used for short-lived projects (error is small)
- Distinction between continuous and discrete rebalancing is seldom used

Debt rebalanced, 3 ways:

First way: stepwise adjust WACC

(this assumes continuous rebalancing):

(a) Unlever: calculate opportunity cost of capital from the existing operations

$$r = r_d \frac{D}{V} + r_e \frac{E}{V}$$

(b) Use this OCC plus project's cost of debt and debt ratio to calculate project's cost of equity using:

$$r_e = r_a + (r_a - r_d) \frac{D}{E}$$

step (a) and (b) can be also be done in terms of β 's, then use CAPM to calculate returns

(c) Relever: calculate after tax WACC using project's costs and weights:

$$WACC = r_e \frac{E}{V} + r_d (1 - \tau) \frac{D}{V}$$

Second way: adjust WACC using Miles-Ezzell formula

(this assumes discrete rebalancing):

(a) Unlever: use data from existing operations to calculate OCC

$$WACC = r_a - \tau r_d \frac{\mathbf{D}}{\mathbf{V}} \left(\frac{(1 + r_a)}{(1 + r_d)} \right)$$

by solving Miles-Ezzell for r_a (use Miles-Ezzell 'in reverse')

(b) Relever: use Miles-Ezzell and OCC plus project's cost of debt and debt ratio to calculate project's WACC:

$$WACC = r_a - \tau r_d \frac{D}{V} \left(\frac{(1+r_a)}{(1+r_d)} \right)$$

Third way: use Adjusted Present Value (APV)

- 1. Calculate OCC using 1 of the methods above
- 2. Discount project's cash flow to find base case NPV
- 3. Discount tax shields at the opportunity cost of capital
- **4.** Multiply PV with $(1 + r_a)/(1 + r_d)$ if debt is rebalanced periodically

Debt amounts predetermined, same 3 ways:

First way: stepwise adjust WACC

(a) Unlever: calculate opportunity cost of capital:

$$r_a = r_e \frac{E}{V_a} + r_d \frac{D - PV(TS)}{V_a}$$
 or $r_a \frac{V_a}{V} = r_e \frac{E}{V} + r_d \frac{D - PV(TS)}{V}$

Not very practical, only used under the Modigliani-Miller assumption that cash flows are perpetuities:

$$r_a = \mathbf{r_d}(1- au) \frac{\mathbf{D}}{\mathbf{V} - au \mathbf{D}} + \mathbf{r_e} \frac{\mathbf{E}}{\mathbf{V} - au \mathbf{D}}$$

(b) Use OCC and project's cost of debt and debt ratio to calculate project's cost of equity using:

$$r_e = r_a + (r_a - r_d) \frac{D - PV(TS)}{E}$$

or under the Modigliani-Miller assumptions:

$$r_e = r_a + (1 - \tau)(r_a - r_d)\frac{D}{E}$$

step (a) and (b) can be also be done in terms of β 's, use CAPM to calculate returns

(c) Relever: calculate after tax WACC using project's costs and weights

$$WACC = r_e \frac{E}{V} + r_d (1 - \tau) \frac{D}{V}$$

Second way: adjust WACC using Modigliani-Miller formula (requires MM assumptions)

(a) Unlever: use data from existing operations to calculate OCC

WACC =
$$r_a(1 - \tau \mathbf{L})$$

by solving MM for r_a (use MM 'in reverse')

(b) Relever: use MM again, with OCC (r_a) and project's debt-to-value ratio to calculate project's WACC:

$$WACC = r_a(1 - \tau L)$$

- ▶ MM assumes debt is predetermined and permanent
- ► It is still a good approximation for projects with limited lives if debt is predetermined

Third way: adjusted present value (APV)

- calculate OCC
- calculate base case NPV
- use predetermined schedule for interest payments
- discount tax shield at the cost of debt

First analyses

Financing rules & discount rates

Calculating project value with different debt ratio

Examples

Example of unlevering β :

If project is in different line of business:

- different business risk
- different asset β
- different opportunity cost of capital

Find asset β from firms in same line of business:

- \blacktriangleright take average of a no. of firms after unlevering $\beta's$
- assumes disturbances cancel out.

Following 3 firms are considered representative of business risk (asset beta) in an industry. Calculate the asset beta.

Firm	Stock β	debt/total value
1	1.35	0.40
2	1.25	0.50
3	1.30	0.55

All debt is rebalanced and can be considered risk free.

The relation between asset β and equity beta is:

$$\beta_a = \beta_d \frac{D}{V} + \beta_e \frac{E}{V}$$

if debt is risk free, this is:

$$\beta_a = \beta_e \frac{E}{V}$$

The calculation becomes:

Firm	Stock β	equity/total value	Asset β
1	1.35	0.60	0.810
2	1.25	0.50	0.625
3	1.30	0.45	0.585
sum			2.020

Gives an average β of 2.02/3=0.67

A worked out example

company data

- ► Transport company, book value €90 million
- debt frequently adjusted and renegotiated
- capital structure constant (rebalanced)
- market value short term debt €20 mill., interest rate = 9%
- market value long term debt €20 mill., interest rate = 11%
- ▶ 10 million shares outstanding, priced at €6 to give 20% return
- tax rate 35%

Project data

- expansion to new geographical area, same business
- expansion has optimal capital structure at 60% debt
- apart from that financial policy unchanged
- debt available at 12%
- investment €50 million
- gives perpetual after tax cash flow of €7 million per year

Question: should company accept project or not?

Analysis

- When should project be accepted?
 - Accept project if NPV > 0
- What do we need to calculate NPV?
 - Proper discount rate or APV
- Does project have different business risk?
 - No, expansion in same business, same risk
- Can we use company cost of capital (WACC)?
 - No, business risk is the same, financial risk is different, different debt ratio
- What procedure do we use?
 - ▶ Debt rebalanced ⇒ stepwise adjust WACC, Miles-Ezzell formula or APV

Calculations

First, make some adjustments to balance sheet:

- 1. Calculate company capital structure at market prices:
 - Market value debt €40 million (20+20, freq. renegotiated)
 - Market value equity 6x10 million = €60 mill.

Balance sheet's right hand side becomes:

Equity	60
Long term debt	20
Short term debt	20
total	100

Gives a company WACC of:

$$WACC = (1 - .35) \times .11 \times .2 + (1 - .35) \times .09 \times .2 + .2 \times .6 = .146$$

Miles-Ezzell calls for 1 cost of debt, use weighted average:

$$.5 \times .11 + .5 \times .09 = .1$$

We can use APV or find discount rate for project with 1 of the 2 methods

First method: stepwise adjust WACC

(this assumes continuous rebalancing):

1. Unlever: use data ZXco's existing operations to find OCC:

$$r_a = \mathbf{r_d} \frac{\mathbf{D}}{\mathbf{V}} + \mathbf{r_e} \frac{\mathbf{E}}{\mathbf{V}} = .1 \frac{40}{100} + .2 \frac{60}{100} = .16$$

2. use OCC and project's cost of debt (.12) to calculate project's cost of equity:

$$r_e = r_a + (r_a - r_d) \frac{D}{E} = .16 + (.16 - .12) \frac{30}{20} = .22$$

3. relever: calculate project's WACC:

$$WACC = (1 - .35) \times .12 \times .6 + .22 \times .4 = .1348 \text{ or } 13.5\%$$

Second method: use Miles-Ezzell

(this assumes discrete rebalancing):

1. Unlever: use ZXco's data to find OCC r:

WACC =
$$r_a - \tau \mathbf{r_d} \frac{\mathbf{D}}{\mathbf{V}} \left(\frac{(1+r_a)}{(1+\mathbf{r_d})} \right)$$

.146 = $r_a - .35 \times .1 \times .4 \times \left(\frac{(1+r_a)}{(1+.1)} \right) \Rightarrow r = .161$

2. Relever: find project's WACC using OCC and project's r_d and L:

$$WACC = .161 - .35 \times .12 \times .6 \times (\frac{1.161}{1.12}) = .1349 \text{ or } 13.5\%$$

Value of perpetual cash flow of €7

- ▶ with discount rate of .135
- \triangleright is 7/.135 = 51.85
- investment is €50,
- \triangleright NVP = 1.85 > 0

Project should be accepted

Third method: use APV

- 1. First calculate base case as if all equity financed using opportunity CoC: 7/.16 = 43.75
- 2. Then calculate tax shield:

$$\tau r_d D = .35 \times .12 \times 30 = 1.26 (D = .6 \times 50)$$

3. Discount at opportunity CoC:

$$1.26/.16 = 7.875$$

4. Multiply PV with $(1 + r_a)/(1 + r_d)$:

$$((1+.16)/(1+.12)) \times 7.875 = 8.16$$

5. Total APV is 43.75 + 8.16 = 51.91, NPV is 1.91, same conclusion: accept project

If the project would be financed with a perpetual loan with

- ▶ the same interest rate but
- ► predetermined amounts instead of the flexible loan used now would the value of the project go up or down? (no calculations necessary)

same interest \rightarrow same tax advantage but fixed \rightarrow safer \rightarrow lower discount rate (r_d instead of r_a) so higher project value

Conclusion: What methods are use in practice?

- Capital structure shows (slow) mean reversion
- means debt ratios are rebalanced

Found on a much wider scale:

- most firms have target debt ratios
- or a target range for their debt ratio

Rebalancing is dominant financial policy WACC is extensively used in practice, together with CAPM
